REGULATED POWER SUPPLY

Voltage regulator provides a constant dc output voltage that is essentially independent of the input voltage, output load current and temperature.
56.1. General

The various power-supply circuits considered in Chapter 5 suffer from the drawback that their dc output voltage changes with changes in load or input voltage. Such a dc power supply is called unregulated power supply. Regulated power supply can be obtained by using a voltage regulator circuit. A regulator is an electronic control circuit which is capable of providing a nearly constant dc output voltage even when there are variations in load or input voltage. A source of regulated dc power is essential for all communication, instrumentation, computers or any other electronic system.

We will consider both linear regulators and switching regulators which are also available in integrated circuit form. In linear regulators, the transistor operates somewhere between saturation and cut-off. It is always ON and dissipates power. Hence, its efficiency (output power/input power) is 50 per cent or less. In switching regulators, the transistor operates like a switch i.e. it is either saturated or cut-off. Hence, its power efficiency is 90 per cent or more.

The linear regulators are of two basic type i.e. series regulators and shunt regulators. Likewise switching regulators can be of three basic types (i) step-down type, (ii) step-up type and (iii) inverting type.

56.2. Voltage Regulation

As stated above, in an unregulated power supply, output voltage changes whenever input supply voltage or load resistance changes. It is never constant. The change in voltage from no-load to full-load condition is called voltage regulation. The aim of a voltage regulator circuit is to reduce these variations to zero or, at least, to the minimum possible value.

The percentage regulation or, simply, regulation of a power supply is given by

\[
\% \text{ regulation} = \left( \frac{V_{\text{max}} - V_{\text{min}}}{V_{\text{max}}} \right) \times 100
\]

where \( V_{\text{max}} \) = maximum dc output voltage and \( V_{\text{min}} \) = minimum dc output voltage.

When we say that 10 V regulated dc power supply has a regulation of 0.005 per cent, it means that dc output voltage will vary within an envelope 0.005 per cent of 10 V.

Now, \( 0.005\% \) of 10 V = \( \frac{V_{\text{max}} - V_{\text{min}}}{V_{\text{max}}} \times 100 \)

\( = 0.0005 \text{ V} = 0.5 \text{ mV} \)

Hence, output voltage will vary by ± 0.25 mV. So, we see that instead of expressing voltage regulation by unwieldy expression 0.005 per cent, we can express it by a simple figure of ± 0.25 mV.

In general, \( \% \text{ regn.} = \frac{V_{\text{NL}} - V_{\text{FL}}}{V_{\text{FL}}} \times 100 \)

where, \( V_{\text{NL}} \) = no-load or open-circuit terminal voltage of the supply (Fig. 56.1).
\( V_{\text{FL}} \) = full-load terminal voltage of the supply

In an ideal or perfectly regulated dc power supply, the percentage voltage regulation is zero. This voltage regulation is also called load regulation.

56.3. Zener Diode Shunt Regulator

A simple shunt voltage regulating system using a zener diode is shown in Fig. 56.2. The
input voltage $V_{in}$, in fact, is the unregulated output of a rectifier. This simple regulator restricts output voltage variations within reasonable limits around $V_{in}$ in the face of changing load current or changing input voltage. Obviously, the Zener diode will regulate so long as it is kept in reverse conduction.

Example 56.1. The Zener diode of Fig. 56.2 has the following ratings:

- $V_z = 6.8$ V at $I_z = 50$ mA
- $r_z = 2$ Ω at $I_z = 50$ mA
- $I_{z(min)} = 5$ mA
- $I_{z(max)} = 150$ mA

What would be the load voltage when load current $I_L$ varies from 10 mA to 120 mA? Also, calculate voltage regulation of the regulator.

**Solution.** We will call $V_z = 6.8$ V and $I_z = 50$ mA as reference values and calculate changes in voltage with respect to these values.

(i) $I_L = 120$ mA

- Obviously, $I_z = 150 - 120 = 30$ mA
- Deviation from 50 mA = $30 - 50 = -20$ mA
- Drops across diode = $I_z r_z = -20 \times 2 = -40$ mV
- $V_L = V_z + I_z r_z = 6.8 + (-40 \times 10^{-3}) = 6.76$ V

(ii) $I_L = 10$ mA

- Now, $I_z = 150 - 10 = 140$ mA
- Deviation from reference value = $140 - 50 = 90$ mA
- Diode drop = $I_z r_z = 90 \times 10^{-3} \times 2 = 0.18$ V
- $V_L = V_z + I_z r_z = 6.8 + 0.18 = 6.98$ V

% regn. = \( \frac{6.98 - 6.76}{6.98} \times 100 = 3.15 \% \)

For many applications, a change in load voltage of 3.15% is acceptable but, in some, it may be intolerable. This regulation can be reduced to 1% or less with the help of circuits discussed below.

### 56.4. Transistor Series Voltage Regulator

The circuit is shown in Fig. 56.3. It is also called *emitter-follower* regulator because the voltage at the emitter follows the base voltage. In this set-up, the transistor behaves like a variable resistor whose resistance is determined by the base current. It is called *pass* transistor because total current to be regulated passes through it.

Keeping in mind the polarities of different voltages, they are related by the equation derived from KVL

\[ V_L + V_{BE} - V_z = 0 \]
When current demand is increased by decreasing \( R_L \), \( V_L \) tends to decrease. As seen from the above equation, it will increase \( V_{BE} \) because \( V_z \) is fixed. This will increase forward bias of the transistor thereby increasing its level of conduction. This, in turn, will lead to decrease in the collector-emitter resistance of the transistor which will slightly increase the input current in order to compensate for decrease in \( R_L \) so that \( V_L = (I_L R_L) \) will remain at a constant value. Incidentally, \( R \) is used for limiting current passing through the Zener diode.

56.5. Controlled Transistor Series Regulator

The circuit employing a second transistor \( T_2 \) as a sensing element is shown in Fig. 56.4. It has the additional feature of control with the help of potentiometer \( R_1 - R_2 \). In the discussion to follow, it will be assumed that \( I \) is much greater than \( I_{B2} \). Now, there is a drop of \( V_L \) on \( (R_1 + R_2) \) and a drop of \( (V_z + V_{BE2}) \) across \( R_2 \).

\[
\frac{V_L}{V_z + V_{BE2}} = \frac{R_1 + R_2}{R_2} \quad \text{or} \quad V_L = \frac{R_1 + R_2}{R_2} (V_z + V_{BE2})
\]

Now, \( (R_1 + R_2) \) and \( (V_z + V_{BE2}) \) both have constant values so that \( V_L \propto 1/R_z \). If the potentiometer is adjusted so that \( R_2 \) decreases, then \( V_L \) increases and vice versa.

Suppose \( R_2 \) is decreased. Then, \( I_c \) increases but \( V_L \) decreases. Decreases in \( I_C \) decreases \( I_{B2} \) and \( I_{C2} \). Assuming \( I_3 \) to be relatively constant (or decreasing only slightly), \( I_{B1} \) is increased thereby decreasing the terminal (collector-emitter) resistance of \( T_1 \). This leads to decrease in \( V_{CE1} \) thereby offsetting the decrease in \( V_L \) which is, therefore, returned to its original value.

In sequential logic, we have

\[
V_L \downarrow \quad I_{B2} \downarrow \quad I_{C2} \downarrow \quad I_{B1} \uparrow \quad V_{CE1} \downarrow \quad V_2 \uparrow
\]

56.6. Transistor Shunt Voltage Regulator

It employs the transistor in shunt configuration as shown in Fig. 56.5.

Since path \( A B \) is in parallel across \( V_L \), we have from Kirchhoff’s Voltage Law

\[
V_L - V_z - V_{BE} = 0
\]

or

\[
V_{BE} = V_L - V_z \quad \text{(fixed)}
\]

Since \( V_z \) is fixed, any decrease or increase in \( V_L \) will have a corresponding effect on \( V_{BE} \). Suppose, \( V_L \) decreases, then as seen from the above relation, \( V_{BE} \) also decreases. As a result, \( I_B \) decreases, hence,
$I_C (= \beta I_B)$ decreases, thereby decreasing $I$ and hence $V_R (= IR)$. Consequently, $V_L$ increases because at all times

\[ V_{in} = V_R + V_L \quad \text{or} \quad V_L = V_{in} - V_R \]

In sequential logic,

- $V_z \downarrow \quad V_{BE} \downarrow \quad I_B \downarrow \quad I_C \downarrow \quad I_R \downarrow \quad V_R \downarrow \quad V_L \uparrow$

Same line of logic applies in case $V_L$ tries to increase.

**Example 56.2.** In the NPN emitter-follower regulator circuit of Fig. 56.6, calculate (i) $V_L$, (ii) $V_{CE}$, (iii) $I_E$ and (iv) power dissipated. Take $V_{BE} = 0.7$ V.

**Solution.**

(i) $V_L = V_{out} = V_Z - V_{BE} = 9 - 0.7 = 8.3$ V

(ii) $V_{CE} = V_{in} - V_{out} = 12 - 8.3 = 3.7$ V

(iii) $I_E = I_L = V_L/R_L = 83$ mA

(iv) Power dissipated = $V_{CE} I_E = 3.7 \times 83 = 310$ mW

**Example 56.3.** Compute the output voltage $V_{out}$ for the op-amp series regulator shown in Fig. 56.7.

**Solution.** We are given that $V_{REF} = 6$ V and $R_2 = R_3 = 1$ K

\[ V_{out} = V_{REF} \left(1 + \frac{R_z}{R_3}\right) = 6(1 + 10/10) = 6 \times 2 = 12 \text{ V} \]

**56.7. Transistor Current Regulator**

The main function of a current regulator is to maintain a fixed current through the load despite variations in the terminal voltage. Such a circuit employing a Zener diode and a PNP transistor is shown in Fig. 56.8. Suppose, due to drop in $V_L$, current $I_L (= I_C)$ is decreased. This will decrease $I_E (= I_C)$. Hence, drop across $R_E$, i.e., $V_{RE}$ will decrease. As per Kirchoff’s Voltage Law

\[-V_{RE} - V_{BE} + V_z = 0, \quad \text{or} \quad V_{BE} = V_z - V_{RE} \]

(fixed)
Hence, a decrease in $V_{RE}$ will increase $V_{BE}$ and, hence, the conductivity of the transistor thereby keeping $I_L$ at a fixed level.

A similar logic applies when there is increase in $V_L$.

56.8. Variable Feedback Regulator

The regulators considered so far provide a non-adjustable output voltage. This would be fine if only single value of regulated voltage is required. Fig. 56.9 shows a feedback regulator which provides different values of regulated dc voltage. In Fig. 56.9, $T_1$ is the pass transistor and $T_2$ is the feedback transistor whose job is to provide and sample output (i.e. load) voltage. It offsets any change in the output voltage. Since potentiometer $R_3$ is connected in parallel with Zener diode $D$, it has Zener voltage $V_z$ applied across it. Voltage across the wiper varies from 0 to $V_z$. Capacitor $C$ ensures that voltage across $D$ and $R_3$ does not change suddenly.

Voltage at the base of $T_2$ is 0.7 V more positive than the voltage at its emitter. Its emitter voltage and hence the base voltage can be changed with the help of $R_3$. Since base of $T_2$ is tied to the output, it is responsible for providing output or load voltage. The voltage $V_{CE1}$ across the pass transistor is given by the difference of input voltage and output voltage. The current through $T_1$ is equal to the load current. $R_2$ prevents saturation of transistors whereas $R_1$ limits the current flowing through $D$.

The working of feedback transistor can be explained as follows:

Since base voltage of $T_2$ is directly related to $V_{out}$, it will change if $V_{out}$ changes. The base and collector of $T_2$ are 180° out of phase with each other. If base voltage increases due to increase in $V_{out}$ collector voltage would decrease. Now, collector of $T_2$ controls base of $T_1$. As the base voltage of $T_1$ decreases, its collector-emitter resistance increases which lowers the load current. This, in turn, lowers the output voltage thereby offsetting the attempted increases in $V_{out}$. The opposite of these steps provides the action of an attempted decrease in output voltage.

Example 56.4. In the variable feedback regulator circuit of Fig. 56.8, $V_{in} = 25$ V, $V_z = 15$ V and $R_L = 1$ K. If the wiper of $R_3$ is adjusted half-way and assuming silicon transistor, compute (i) $V_{out}$ (ii) $I_L$ (iii) $I_{E1}$ (iv) $P_1$.

Solution. (i) $V_{out} = \text{voltage at wiper} + V_{BE2} = (15/2) + 0.7 = 8.2$ V
(ii) $I_L = \frac{V_{out}}{R_L} = 8.2 \text{ V}/1 \text{ K} = 8.2 \text{ mA}$
(iii) $I_{E1} = I_L = 8.2 \text{ mA}$
(iv) $V_{CE1} = V_{in} - V_{out} = 25 - 8.2 = 16.8$ V
∴ $P_1 = 16.8 \text{ V} \times 8.2 \text{ mA} = 140 \text{ mW}$

56.9. Basic Op-amp Series Regulator

Its circuit is shown in Fig. 56.10 and its operation is as follows:

The potentiometer $R_2 - R_3$ senses any change in output voltage $V_{in}$ and provides an error voltage $V_{REF} = V_{in} - V_{out}$. The error voltage is amplified by the op-amp and the output is then divided by $R_1 - R_2$ and fed back to the inverting input of the op-amp. This action provides voltage $V_{out}$ which is equal to $V_{in} - V_{REF}$. Hence, $V_{out}$ remains constant and is equal to $V_{in} - V_{REF}$.
put voltage $V_{out}$. When $V_{out}$ attempts to decrease because of decrease in $V_{in}$ or because of the increase in $I_L$, a proportional voltage decrease is applied to the inverting output of the op-amp by the potentiometer. Since, the other op-amp input is held by the Zener voltage at a fixed reference voltage $V_{REF}$, a small difference voltage (called error voltage) is developed across the two inputs of the op-amp. This difference voltage is amplified and op-amp’s output voltage increases. This increase in voltage is applied to the base of $T_1$ causing the emitter voltage (=$V_{out}$) to increase till the voltage to the inverting input again equals the reference (Zener) voltage. This action offsets attempted decrease in the output voltage thus keeping it almost constant. The opposite action occurs if the output voltage tries to increase.

**Calculations**

It will be seen that the op-amp of Fig. 56.10 is actually connected as a non-inverting amplifier where $V_{REF}$ is the input at the noninverting terminal and the $R_2/R_3$ voltage divider forms the negative feed-back network. The closed-loop voltage gain is given by $A = 1 + (R_2/R_3)$. Neglecting base-emitter voltage of $T_1$, we get

$$V_{out} = V_{REF} (1 + R_2/R_3)$$

It is seen that $V_{out}$ depends on Zener voltage and potential divider resistors $R_2$ and $R_3$ but is independent of input voltage $V_{in}$.

### 56.10. Basic Op-amp Shunt Regulator

Such a shunt type linear regulator is shown in Fig. 56.11. Here, the control element is a series resistor $R_1$ and a transistor $T_1$ in parallel with the load. In such a regulator, regulation is achieved by controlling the current through $T_1$.

**Working**

When output voltage tries to decrease due to change in either the input voltage or load current or temperature, the attempted decrease is sensed by $R_3$ and $R_4$ and applied to the non-inverting input of the op-amp. The resulting difference in voltage reduces the op-amp’s output, driving $T_1$ less thus reducing its collector current (shunt current), and increasing its collector-to-emitter resistance. Since collector-to-emitter resistance acts as a voltage divider with $R_4$, this action offsets the attempted decrease in output voltage and hence, maintains it at a constant value. The opposite action occurs when output voltage tries to increase. The shunt regulator is less efficient than the series type but offers inherent short-circuit protection.

### 56.11. Switching Regulators

In the linear regulators considered so far, the control element *i.e.* the transistor conducts all the time, the amount of conduction varying with changes in output voltage or current. Due to continuous power loss, the efficiency of such a regulator is reduced to 50 per cent or less.

A switching regulator is different because its control element operates like a switch *i.e.* either it is saturated (closed) or cut-off (open). Hence, there is no unnecessary wastage of power which results in higher efficiency of 90% or more.

Switching regulators are of three basic types: (i) step-down regulator, (ii) step-up regulator and (iii) inverting regulator.
56.12. Step-down Switching Regulator

In this regulator (Fig. 56.12), $V_{out}$ is always less than $V_{in}$. An unregulated positive dc voltage is applied to the collector of the NPN transistor. A series of pulses from an oscillator is sent to the base of transistor $T$ which gets saturated (closed) on each of the positive pulses. It is so because an NPN transistor needs a positive voltage pulse on its base in order to turn ON. A saturated transistor acts as a closed switch, hence it allows $V_{in}$ to send current through $L$ and charge $C$ to the value of output voltage during the on-time ($T_{ON}$) of the pulse. The diode $D_1$ is reverse-biased at this point and hence, does not conduct.

Eventually when positive pulse turns to zero, $T$ is cut-off and acts like an open switch during the off period ($T_{OFF}$) of the pulse. The collapsing magnetic field of the coil produces self-induced voltage and keeps the current flowing by returning energy to the circuit.

The value of output voltage depends on input voltage and pulse width i.e. on-time of the transistor. When on-time is increased relative to off-time, $C$ charges more thus increasing $V_{out}$. When $T_{ON}$ is decreased, $C$ discharges more thus decreasing $V_{out}$. By adjusting the duty cycle ($T_{ON}/T$) of the transistor, $V_{out}$ can be varied.

$$V_{out} = V_{in} \left( \frac{T_{ON}}{T} \right)$$

where $T$ is the period of the ON-OFF cycle of the transistor and is related to frequency by $T = 1/f$. Also, $T = T_{ON} + T_{OFF}$ and the ratio ($T_{ON}/T$) is called the duty cycle.

The regulating action of the circuit is as follows:

When $V_{out}$ tries to decrease, on-time of the transistor is increased causing an additional charge on the capacitor $C$ to offset the attempted decrease. When $V_{out}$ tries to increase, $T_{ON}$ of the transistor is decreased causing $C$ to discharge enough to offset the attempted increase.

56.13. Step-up Switching Regulator

The circuit is shown in Fig. 56.13. When transistor $T$ turns ON on the arrival of the positive pulse at its base, voltage across $L$ increases quickly to $V_{in} - V_{CE(sat)}$ and magnetic field of $L$ expands quickly. During on-time of the transistor, $V_L$ keeps decreasing from its initial maximum value. The longer transistor is ON, the smaller $V_L$ becomes.

When transistor turns OFF, magnetic field of $L$ collapses and its polarity reverses so that
its voltage adds to the input voltage thus producing an output voltage greater than the input voltage. During off-time of the transistor, $D_2$ is forward-biased and allows $C$ to charge. The variations in $V_{out}$ due to charging and discharging action are sufficiently smoothed by filtering action of $L$ and $C$.

It may be noted that shorter the on-time of the transistor, greater the inductor voltage and hence greater the output voltage (because greater $V_L$ adds to $V_{in}$). On the other hand, the longer the on-time, the smaller the inductor voltage and hence, lesser the output voltage (because smaller $V_L$ adds to $V_{in}$).

The regulating action can be understood as follows:

When $V_{out}$ tries to decrease (because of either increasing load or decreasing $V_{in}$), transistor on time decreases thereby offsetting attempted decrease in $V_{out}$. When $V_{out}$ tries to increase, on-time increases and attempted increase in $V_{out}$ is offset.

As seen, the output voltage is inversely related to the duty cycle.

\[ V_{out} = V_{in} \left( \frac{T}{T_{ON}} \right) \]

### 56.14. Inverting Switching Regulator

The basic diagram of such a regulator is shown in Fig. 56.14. This regulator provides an output voltage that is opposite in polarity to the input voltage.

When transistor $T$ turns ON by the positive pulse, the inductor voltage $V_L$ jumps to $V_{in} - V_{CE(sat)}$ and the magnetic field of the inductor expands rapidly. When transistor is ON, the diode $D_2$ is reverse-biased and $V_L$ decreases from its initial maximum value. When transistor turns OFF, the magnetic field collapses and inductor’s polarity reverses. This forward-biases $D_2$, charges $C$ and produces a negative output voltage. This repetitive ON-OFF action of the transistor produces a repetitive charging and discharging that is smoothed by $LC$ filter action. As in the case of a step-up regulator, lesser the time for which transistor is ON, greater the output voltage and vice versa.

### 56.15. IC Voltage Regulators

Due to low-cost fabrication technique, many commercial integrated-circuit (IC) regulators are available since the past two decades. These include fairly simple, fixed-voltage types of high-precision regulators. These IC regulators have much improved performance as compared to those made from discrete components. They have a number of unique build-in features such as current limiting, self-protection against overtemperature, remote control operation over a wide range of input voltages and foldback current limiting.

Now we will study the following types of IC voltage regulators: (1) fixed positive linear voltage regulators, (2) fixed negative linear voltage regulators, (3) adjustable positive linear voltage regulators, and (4) adjustable negative linear voltage regulators.

### 56.16. Fixed Positive Linear Voltage Regulators

There are many IC regulators available in the market that produces a fixed positive output voltage. But 7800 series of IC regulators is representative of three terminal devices that are available
with several fixed positive output voltages making them useful in a wide range of applications. Fig. 56.15 (a) shows a standard configuration of a fixed positive voltage IC regulator of 7800 series. Notice that it has three terminals labelled as input, output and ground. The last two digits (marked xx) in the part number designate the output voltage. For example, IC 7805 is a +5 V regulator. Similarly IC 7812 is a +12 V regulator and IC 7815 is a +15 V regulator. The capacitor C1 (typically 0.33 µF) is required only if the power supply filter is located more than 3 inches from the IC regulator. The capacitor C2 (typically 0.01 µF) acts basically as a line filter to improve transient response.

Fig. 56.15 (b) shows the part number and the output voltage of 7800 series IC voltage regulators. As seen from this figure, the 7800 series has IC regulators that can produce output voltages ranging from +5.0 to +24.0 volt. It may be carefully noted that although these regulators are designed primarily to produce fixed output voltage but they can be used with external components to obtain adjustable output voltage and current.

Fig. 56.16 shows the circuit indicating the use of 78XX as an adjustable voltage regulator. The output voltage is given by the equation,

\[ V_{out} = V_{fixed} + \left( \frac{V_{fixed}}{R_1} + I_Q \right) R_2 \]

For example, for a 7805 IC regulator, \( V_{fixed} = 5 \text{ V} \). Let \( R_1 = R_2 = 1 \text{ k} \Omega \) and \( I_Q = 5 \text{ mA} \), then its output voltage is,

\[ V_{out} = 5 + \left( \frac{5}{1 \text{ k} \Omega} + 5 \text{ mA} \right) \times 1 \text{ k} \Omega = 15 \text{ V} \]

Thus output voltage of IC 7805 regulator can be adjusted anywhere between 5 V to 15 V.

This example indicates that the output of IC 7805 regulator is adjusted to 15 V using external resistances \( R_1 \) and \( R_2 \).

The standard 7800 series can produce output current in excess of 1 A when used with adequate
Regulated Power Supply

heat sink. It is available in aluminium can package TO-3 (indicated by $K$ in the part number) and plastic package TO-220 (indicated by $T$ in the part number). The 78L00 series can provide up to 100 mA and is available in TO-92 and metal TO-39 low profile packages. The 78M00 series can provide up to 0.5 A and is available in plastic TO-202 package. Fig. 6.17 shows the typical metal and plastic packages for the IC voltage regulators.

It may be noted that the input voltage for the IC regulator must be at least 2 V above the output voltage. This is required in order to maintain regulation. The input voltage should not be more than 35 or 40 volts depending upon the part number. The circuit inside all the IC regulators have internal thermal overload protection and short-circuit current-limiting features. Thermal overload in a IC regulator occurs whenever the internal power dissipation becomes excessive and the temperature of the device exceeds a certain value.

In India, Bharat Electronic Limited, Bangalore manufactures the IC voltage regulators with output voltages of 5 and 12 V. These are available in the market with part numbers BEL 7805 and BEL 7812 respectively.

Fig 56.18 shows a picture of a transformer bridge rectifier and voltage regulator in a dc power supply.

56.17. Fixed Negative Linear Voltage Regulators

The 7900 series is typical of three-terminal IC regulators that provide a fixed negative output voltage. This series is a negative-voltage counterpart of the 7800 series and shares most of the same features, characteristics and package types. Fig. 56.19 $(a)$ indicates the standard configuration and Fig. 56.19 $(b)$, the part numbers with corresponding output voltages that are available in 7900 series.

The capacitor $C_1$ (typically 0.22 µF) is required only if the power supply filter is located more than 3 inches away from the IC regulator. The capacitor $C_2$ (typically 1 µF) is required for stability of the output voltage. Both capacitors $C_1$ and $C_2$ must be solid tantalum capacitors.

Fig. 56.20 shows the use of 79XX to produce an adjustable output voltage. The capacitor $C_3$ (typically 25 µF) improves the transient response of the output voltage. The output voltage is given by the equation,

$$V_{\text{out}} = V_{\text{fixed}} \left(\frac{R_1 + R_2}{R_2}\right)$$

The recommended value of $R_2$, for 7905 is 300 Ω, for 7915, its value is 750 Ω and for 7915 is 1 kΩ.

In India, BEL manufactures IC regulators with output voltage of −5 V and −12 V. These are available in the market with part numbers BEL 7905 and BEL 7915 respectively.

### 56.18. Adjustable Positive Output Linear Voltage Regulators

We have already seen in Art. 56.16 that by adding external resistors, we can adjust the output voltage of 7800 series IC regulators higher than their fixed (or set) voltages. For example, the output voltage of 7805 can be adjusted higher than 5 V. But the performance and reliability of 7800 series to produce voltage higher than its fixed value is not considered to be good.

The LM 317 and LM 723 are IC regulators whose output voltage can be adjusted over a wide range. The output voltage of LM 317 can be adjusted from 1.2 V to 37 V, it can supply output current of 100 mA and is available in TO-92 package *i.e.*, it is also a 3 terminal IC regulator. On the other hand, the output voltage of LM 723 can be adjusted from 2 V to 37 V, it can supply output current of 150 mA without external transistor. But with the addition of external transistor, the output current capability can be increased in excess of 10 A. The LM 723 is available in dual-in-line package and in a metal can package.

Fig. 56.21 (a) shows the LM 317 connected to the external resistors $R_1$ and $R_2$ to produce an adjustable output voltage.
In operation, the LM 317 develops a constant 1.25 V reference voltage \( V_{\text{REF}} \) between the output and adjustment terminal. This constant reference voltage produces a constant current, \( I_{\text{REF}} \) through \( R_1 \), regardless of the value of \( R_2 \). Fig. 56.20. Notice that the value of current through \( R_2 \) is the sum of \( I_{\text{REF}} \) and \( I_{\text{ADJ}} \), where \( I_{\text{ADJ}} \) is a very small current at the adjustment terminal. The value of \( I_{\text{ADJ}} \) is typically around 100 µA. It can be shown that the output voltage,

\[
V_{\text{out}} = V_{\text{REF}} \left( 1 + \frac{R_2}{R_1} \right) + I_{\text{ADJ}} \cdot R_2
\]

It is evident from the above equation that the output voltage is a function of \( R_1 \) and \( R_2 \). Usually the value of \( R_1 \) is recommended to be around 220 Ω. Once the value of \( R_1 \) is set, the output voltage is adjusted by varying \( R_2 \).

**Example 56.5.** Calculate the minimum and maximum output voltages for the IC voltage regulator shown in Fig. 56.22. Assume \( I_{\text{ADJ}} = 100 \) µA, \( V_{\text{in}} = +35 \) V.

**Solution.** The equation for output voltage of the IC voltage regulator is given by,

\[
V_{\text{out}} = V_{\text{REF}} \left( 1 + \frac{R_2}{R_1} \right) + I_{\text{ADJ}} \cdot R_2
\]

When \( R_2 \) is set at its minimum value (i.e. 0 Ω), the output voltage,

\[
V_{\text{out(min)}} = 1.25 \left( 1 + \frac{0}{220} \right) + (100 \times 10^{-6}) \times 0
\]

\[
= 1.25 \text{ V}
\]

When \( R_2 \) is set at its maximum values (i.e. 5 kΩ), the output voltage,

\[
V_{\text{out(max)}} = 1.25 \left( 1 + \frac{5000}{220} \right) + (100 \times 10^{-6}) \times 5000
\]

\[
= 29.66 + 0.5 = 30.16 \text{ V}
\]

### 56.19. Adjustable Negative Output Linear Voltage Regulators

A good example of this type of regulators is LM 337. The regulator is a negative output counterpart of LM 317. The LM 337 (like LM 317) requires two external resistors for adjustment of output.
voltage as shown in Fig. 56.23. The output voltage can be adjusted anywhere from $-1.2 \text{ V}$ to $-37 \text{ V}$ depending upon the external resistor values.

The LM 723 can also be used as an adjustable negative output voltage regulator. The output voltage of this IC regulator can be adjusted anywhere from $-2.0 \text{ V}$ to $-37 \text{ V}$ depending upon the external resistor values.

**56.20. Use of External Pass Transistor with Linear Voltage Regulators**

We have already mentioned in the last two articles that a linear voltage regulator (7800 and 7900 series) is capable of delivering only a certain amount of output current to a load. For example, the 7800 series regulators can handle a maximum output current of at least 1.3 A and typical 2.5 A. If the load current exceeds the maximum allowable value, there will be a thermal overload and the regulator will shut down. A thermal overload condition means that there is excessive power dissipation inside the regulator.

If an application requires a larger value of load current than the maximum current that the regulator can deliver, we will have to use an external pass transistor as shown in Fig. 56.24. The value of $R_{\text{ext}}$ (current-sensing resistor) determines the value of current at which the external pass transistor ($T_{\text{ext}}$) begins to conduct because it sets the base-to-emitter voltage of the transistor.

As long as the current is less than the value set by $R_{\text{ext}}$, the transistor $T_{\text{ext}}$ is off and the regulator operates normally. This is because the voltage drop across $R_{\text{ext}}$ is less than 0.7 V (i.e. the base to emitter voltage required to turn $T_{\text{ext}}$ on). The value of $R_{\text{ext}}$ is determined by the equation $R_{\text{ext}} = 0.7 \text{ V}/I_{\text{max}}$ where $I_{\text{max}}$ is the maximum value of current that the voltage regulator is to handle internally.

When the current is sufficient to produce at least a 0.7 V drop across $R_{\text{ext}}$, the transistor $T_{\text{ext}}$ turns on and conducts any current in excess of $I_{\text{max}}$. The transistor $T_{\text{ext}}$ will conduct current depending on the load requirement. For example, if the total load current is 5 A and $I_{\text{max}}$ was selected to be 1 A, then the external pass Transistor ($T_{\text{ext}}$) will conduct 4 A of current through it.

It may be noted that the external pass transistor is a power transistor with heat sink that must be capable of handling a maximum power given by the equation,

$$P_{\text{ext}} = I_{\text{ext}}(V_{\text{in}} - V_{\text{out}})$$

One major drawback of the circuit shown in Fig. 56.24 is that the external pass transistor is not protected from excessive current, such as would result from a shorted output. This drawback can be overcome by using an additional current limiting circuit as shown in Fig. 56.25.

The operation of this circuit may be explained as follows. The current sensing resistor, $R_{\text{lim}}$ sets the base-to-emitter voltage of $T_{\text{lim}}$. The base-to-emitter voltage of $T_{\text{ext}}$ is now determined by $\left(V_{\text{bem}} - V_{\text{bem}}\right)$ because they have opposite polarities. So for normal operation, the drop across $R_{\text{ext}}$ must be sufficient to overcome the opposing drop across $R_{\text{lim}}$. 
If the current through $T_{ext}$ exceeds a certain maximum value, $(I_{ext(\text{max})})$ because of a shorted output or a faulty load, the voltage across $R_{\text{lim}}$ reaches 0.7 V and turns $T_{\text{lim}}$ on. As a result, $T_{\text{lim}}$ now conducts current away from $T_{ext}$ and through the regulator. This forces a thermal overload to occur and shut down the regulator. Remember, the IC voltage regulator circuitry is internally protected from thermal overload as part of its design. This way the external pass transistor is protected from excessive current.

### 56.21. Use of Linear Voltage Regulators as a Current Regulator

The 3-terminal linear voltage regulator can be used as a current source when an application requires that a constant current be supplied to a variable load. The basic circuit is shown in Fig. 56.26. Here $R_1$ is the current-setting resistor. The regulator provides a fixed output voltage, $V_{\text{out}}$ between the ground terminal and the output terminal. However, it may be noted that the ground pin of the regulator is not connected to the circuit ground. The constant current supplied to the load, is given by the equation,

$$I_L = \frac{V_{\text{out}}}{R_L} + I_Q$$

Usually the current, $I_Q$ is very small as compared to the output current and hence can be neglected, therefore

$$I_L = \frac{V_{\text{out}}}{R_L}$$

For example, if we use 7805 regulator to provide a constant current of 1 A to a variable load, then

$$R_1 = \frac{5}{1} = 5 \, \Omega$$

Please note that input voltage must be at least 2 V greater than the output voltage. Thus for 5 V regulator, $V_{\text{in}}$ must be greater than 7 V.

### 56.22. Switching Voltage IC Regulators

There are several switching voltage IC regulators available in the market. The choice depends upon the desired application and the cost. However, we will illustrate it with the IC 78S40. This device is a universal device that can be used with external components to provide step-up, step down and inverting operation.

Fig. 56.27 shows the internal circuitry of the IC 78C40. The circuitry can be compared to the basic switching regulators discussed in Art. 56.12, 56.13, and 56.14. As seen from this diagram,
oscillator and comparator functions are directly comparable. The logic gate and flip-flop in the 78S40 were not included in the basic circuit of Fig. 56.12, but they provide additional regulation. Transistor $T_1$ and $T_2$ perform the same function as $T$ in the basic circuit. The 1.25 V reference block in the 78S40 has the same purpose as that of the zener diode in the basic circuit and diode $D_1$ in the 78S40 corresponds to $D_1$ in the basic circuit.

The circuitry of 78S40 has also an uncommitted or unused OP-AMP. We require external circuitry to operate this device as a regulator.

Fig. 56.27

Fig. 56.28
Fig. 56.28 shows the external connections of the IC 78S40 for a step-down switching regulator configuration. Note that in this configuration the circuit produces an output voltage which is less than input voltage.

Fig. 56.28 shows the IC 78S40 connected to the external components for a step-up switching regulator configuration. In this case the output voltage is greater than the input voltage. An inverting configuration is also possible but is not shown here.

In both the circuits of Fig. 56.27 and Fig. 56.28, the capacitor $C_T$ (called timing capacitor) controls the pulse width and frequency of the oscillator and thus establishes the on-time of transistor $T_1$. The voltage across the resistor $R_{CS}$ (called current-sensing resistor) is used internally by the oscillator to vary the duty cycle based on the desired peak current. The voltage divider made up of $R_1$ and $R_2$ reduces the output voltage to a value equal to the reference voltage. If the output voltage ($V_{out}$) exceeds its set value, the output of the comparator switches to the low state, disabling the gate to turn $T_2$ off until the output decreases. This regulating action is in addition to that produced by the duty cycle variation of the oscillator.

**Tutorial Problems No. 56.1**

1. The Zener diode of Fig. 56.30 has the following ratings:

\[ V_z = 15 \text{ V} \quad \text{at} \quad I_z = 17 \text{ mA} \]

\[ r_z = 14 \Omega \quad \text{at} \quad I_z = 17 \text{ mA} \]

\[ I_{z_{(min)}} = 0.25 \text{ mA} \quad I_{z_{(max)}} = 66 \text{ mA} \]

What would be the load voltage when load current $I_L$ varies from 1 mA to 60 mA. Also calculate the voltage regulation of the regulator.

\[ (14.846 \text{ V}, 15.672 \text{ V}, 5.27\%) \]
2. Determine the output voltage, \( V_{\text{out}} \), for the op-amp series regulator shown in Fig. 56.31.

(7.3 V)

3. Calculate the minimum and maximum output voltages for the IC voltage regulator shown in Fig. 56.32. Assume \( I_{\text{ADJ}} = 50 \, \mu\text{A}, \) \( V_{\text{in}} = +35 \, \text{V}, \) \( V_{\text{REF}} = 1.2 \, \text{V} \)

(1.25 V, 12.71 V)

4. Fig. 56.33 shows the circuit of a current regulator. What value of \( R_1 \) is necessary to provide a constant current of 1 A.

(12 \, \Omega)

**OBJECTIVE TESTS – 56**

1. The main job of a voltage regulator is to provide a nearly—output voltage.
   (a) sinusoidal  (b) constant  
   (c) smooth  (d) fluctuating.

2. A 10-V dc regulator power supply has a regulation of 0.005 per cent. Its output voltage will vary within an envelope of ................. millivolt.
